Percutaneous biopsy (PB) is a procedure to obtain a tissue sample for histopathologic examination. Sometimes, a PB is repeated when a histopathologic diagnosis is not definitive; it is usually accepted that the procedure is indicated when neoplastic disease is suspected or strongly suspected and when a rapid diagnosis is required. There are three kinds of techniques used to obtain the sample: transbronchial, transesophageal, and transperitoneal. Each technique has a different risk of complications and is used for different purposes. This procedure, with some exceptions, is usually performed under fluoroscopic guidance to reduce complications and localize the lesion. Samples obtained by biopsy are subjected to histopathologic examination, which is the only method to confirm a neoplastic disease. In the last decade, great technological innovations have enabled to obtain the samples under real-time ultrasonography guidance. Histopathologic examination of samples can be performed by different methods: direct examination and cytologic study, immunohistochemistry, and molecular biology techniques. This review analyzes the most important aspects of the PB technique. Homologous recombination is required for functional intercellular communication in *Candida albicans*. Genetic modification of the fungal pathogen *Candida albicans* has been carried out using homologous recombination between related diploid strains, driven either by the URA3 or the HIS3 locus. Successful integration of the target gene at the URA3 locus using this strategy resulted in the production of two copies of the gene in individual daughter cells. We show that such clones produce a distinct pattern of extracellular activities, based on arginine deiminase and protease activities, a trait that was stable for up to 65 generations of progeny. Electrophoretic analysis of products from a specific recombination event between HIS3 and URA3 demonstrated that a His-tagged enzyme was produced following transformation.
